***Abstract*—Public health awareness is an important part of preventive healthcare. Early detection of symptoms can lessen disease severity, cut healthcare costs, and lower mortality rates. However, challenges such as limited access to healthcare services, medical illiteracy, language barriers, and delayed diagnosis still exist, especially in low-resource and crowded areas. Additionally, many people depend on unverified sources for health information. This paper suggests an AI-driven public health chatbot for disease awareness. It combines conversational AI with machine learning for predictions. The system uses a K-Nearest Neighbors (KNN) classifier trained on a dataset of over 50 common diseases to suggest possible conditions based on symptoms reported by users. To improve accessibility, the chatbot can interact in multiple languages and accept voice input.**

The system uses the Claude API to provide clear and user-friendly explanations of predicted conditions while following ethical medical guidelines. It presents predicted diseases along with confidence scores and preventive tips to help users understand better. Experimental evaluation shows that the chatbot is effective at identifying potential diseases and raising awareness. The proposed system serves as an early guidance tool but does not replace a professional medical diagnosis.

The proposed system has been built using a modular architecture that includes five components which are user interface, input processing, machine learning prediction, conversational AI, and output layers. The system uses a layered design that enables both scalability and maintainability while creating distinct operational areas. The machine learning component analyzes symptom data to generate predictions, while the conversational layer translates these outputs into understandable responses for users. The system improves its usability and trustworthiness through its combination of prediction methods which can be interpreted and its natural language processing capabilities. The system implements ethical safeguards which include data privacy protection and transparency measures and medical disclaimers to enable responsible use of the system in public health settings.

I. Introduction

The current healthcare systems in the world are being strained more than ever by the high population growth, urbanization, and lifestyle changes as well as the growing prevalence of the communicable and non-communicable diseases. Global health reports have indicated that a high number of the population, particularly those in developing and low resource areas, lack access to primary healthcare services on time [4]. A shortage of medical staff, a long ratio of patients to doctors as well as insufficient health care facilities usually lead to late diagnosis and treatment which even worsen the severity of diseases and the cost of care.

Lack of public health awareness is a cause of a significant portion of this problem. People are likely to disregard the initial symptoms of a disease, including mild fever, cough, fatigue, headache, or shortness of breath as insignificant. Research has shown that one of the most frequent reasons of disease progression and higher mortality rates is the late medical appointment because of the lack of symptom knowledge [1]. Moreover, based on increased reliance on internet searches and social media use as a source of health information, there has been a lot of misinformation, false self-diagnosis and unfounded anxiety among users.

Artificial Intelligence (AI) and Machine Learning (ML) are the new transformative technologies of the healthcare sphere in recent years. The medical imaging, disease prediction, patient monitoring, decision support, and healthcare management are becoming increasingly explored with the help of AI-based systems [3]. These technologies will make it possible to analyze the data based on data and make decisions quickly and use healthcare solutions at scale. AI-powered health chatbots are one of the most popular types of AI applications because of the opportunity to have real-time interactions, 24-hour availability, and affordable health assistance [2].

Health chatbots are digital assistants, which communicate with the user in a natural language to give symptom-based advice, health education, and preventive advice. Studies have indicated that properly designed healthcare chatbots can make a substantial contribution to enhancing the level of awareness of various diseases at early stages, decreasing unnecessary referrals to hospitals, and assist healthcare organizations by managing non-essential cases [2], [3]. The current chatbot systems, however, mostly use conversational language models without using structures of medical prediction systems. These kinds of systems can produce fluent responses, however, they can generally not be explained and do not provide medical reasoning that is reliable and useful in healthcare use cases [1].

In order to overcome these weaknesses, the desire to have hybrid systems that integrate structured machine learning models with conversational artificial intelligence arises. Symptom based disease prediction K-Nearest Neighbors (KNN) are especially salient to interpretable ML algorithms, which can be rationally thought of in terms of similarity between symptom patterns [5]. Meanwhile, conversational AI can contribute to the engagement of users by formulating technical outputs in

a comprehensible and empathetic format.

Out of these observations, this paper makes a proposal of an AI-driven Public Health Chatbot on Disease Awareness. The suggested system applies to a KNN classifier that was trained to forecast possible health conditions from symptoms that have been reported by the user using a set of over 50 prevalent diseases. To be inclusive and accessible, the chatbot is multilingual and allows voice entries of symptoms and a mobile-friendly user interface, which is in line with human-centered AI and digital health [4]. The integration with the Claude API enables conversational interaction by providing clear and user-friendly explanations and fully respecting medical ethical limits.

The key objective of the suggested system is to promote the effective level of disease awareness and promote regular medical visits. The chatbot will be created as a strict public health awareness and guidance tool and will not substitute professional medical diagnosis. The proposed solution, as a combination of interpretable machine learning, conversational AI, and ethical design principles, is going to add to the expanding body of research in digital public health and AI-enhanced healthcare support systems.

II. RELATED WORK

The use of Artificial Intelligence in healthcare is not a new concept that has been actively discussed during the last several decades, as research has transformed into rule-based expert systems and further developed into machine learning and conversational AI. First generation healthcare decision-support systems mostly relied on expert systems that operated using rules, meaning the medical knowledge was coded into rules that were designed by domain experts. Even though these systems worked well in restricted diagnostic cases, they were characterised by significant weaknesses that included inflexibility, inability to scale, and inability to adapt medical knowledge as new diseases and symptoms came into picture [5]. Since healthcare is an ever-changing field, such restrictions decreased the viability of rule-based methods in the long run.

Disease prediction and medical decision support Machine learning models became an increasingly popular method with the development of data-driven methods. Naive Bayes, Decision Trees, Support Vector Machines (SVM), and Random Forests algorithms became very popular in the classification of diseases based on their symptoms and clinical data [5]. Such methods were found to have better prediction accuracy than rule based systems. Nevertheless, it was pointed out in some studies that most of these models needed huge data volumes, a great number of feature engineering, and complicated parameter adaptation, which restricted their practical use in lightweight and real-time healthcare frameworks [3]. As well, not all advanced models were interpretable, an invaluable feature in the healthcare system where users and practitioners need the ability to gain insight into the logic behind predictions.

Researchers have begun to pay more attention to AI-based healthcare chatbots as a potential way of enhancing accessibility and patient interaction in the recent years. Research has indicated that chatbots have been useful in helping to check symptoms, providing health education, booking appointments as well as following up on patients [2]. Chatbots can come in handy especially when addressing non-critical health questions, which would ease the workload of healthcare professionals and hospitals. Chatbots based on Large Language Models (LLM) have proven their capacity to talk and engage with users since they are able to produce context-aware and fluent responses [2].

Nevertheless, various studies warn that conversational AI systems cannot be used to support credible healthcare usage. Devoid of formal medical logic or predictive algorithms, chatbots can generate unclear, inconsistent or incorrect medical information [1]. This fact clarifies why there is a need to combine conversations with structured machine learning models, which offer explainable and data-driven predictions. Studies highlight that when predictive analytics is used with conversational interfaces, more trustful and user-friendly healthcare systems are achieved [3].

Deep learning methods have also found broad use in medical fields, especially in medical imaging, time-series health sensors and disease crossover prediction. Although deep learning models can be highly accurate, they are computationally intensive and can only work with large labeled datasets and cannot be applied to the public health of real-time and low-resource environments [4]. Consequently, more basic and readable algorithms are still applicable towards the disease prediction tasks that are based on symptoms.

K-Nearest Neighbors (KNN) has long been considered to be an example of successful and easy to comprehend algorithms used in the traditional machine learning approach to classification problems of a categorical and symptom based nature [5]. KNN does not have a very complicated principle since similarity plays a central role but is also intuitive and transparent, which is especially crucial in healthcare settings. A number of articles point out that KNN is a good disease prediction algorithm when there is intersecting overlap of symptoms in two or more diseases, as it intuitively addresses the problem of ambiguity by asking the user to look at a number of nearest neighbors [3].

The accessibility and ethical considerations have also become the focus of healthcare AI studies. According to the World Health Organization, digital health solutions should be open, transparent, and ethically constructed to prevent harm and abuse [4]. It is suggested that multilingual support, voice-to-text, and explicit medical disclaimers should be implemented to make it accessible to various groups of people and avoid excessive use of automated systems.

The proposed AI Driven Public Health Chatbot of Disease Awareness is based on the findings of the existing literature since it is a hybrid solution, including a KNN-based disease prediction model and a conversational AI implemented via the Claude API. The method is a solution to the shortcomings of the purely conversational chatbots whilst preserving interpretability, accessibility, and ethical accountability, which are

highlighted in previous studies [1]-[5].

III. System Architecture

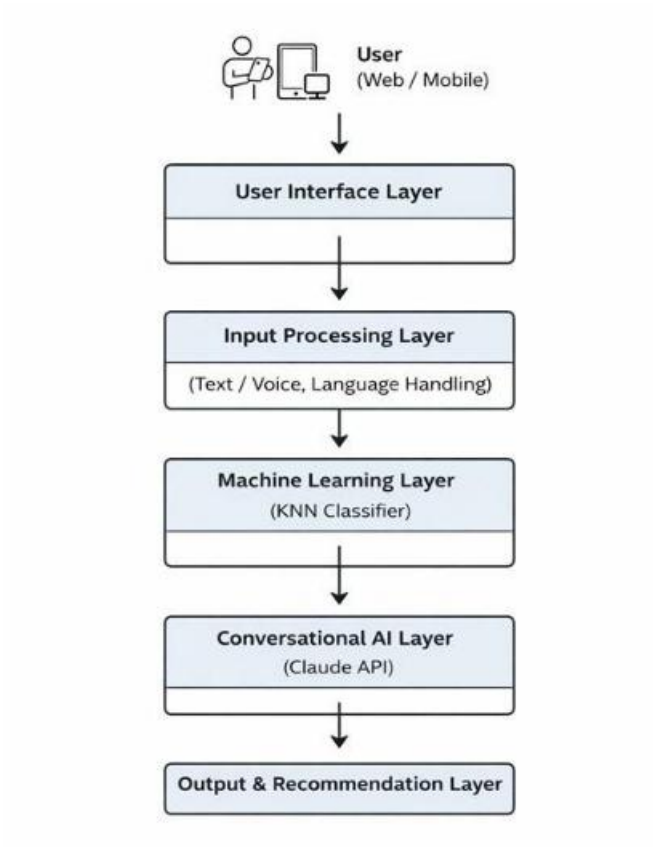

Fig. 1. Architecture of the AI-Driven Public Health Chatbot

The proposed AI Driven Public Health Chatbot system architecture of Disease Awareness is developed with a layered and modular system architecture to provide the level of scalability, interpretability, and maintainability. The healthcare AI systems of today are more focused on the use of modular architectures that isolate the process of data acquisition, generation of intelligence, and interaction with users in order to enhance transparency and ethical regulation [3], [4]. Based on these principles, the proposed system will be arranged into five large layers: User Interface Layer, Input Processing Layer, Machine Learning Prediction Layer, Conversational AI Layer, and Output and Recommendation Layer.

User Interface Layer is the main point of interaction between the user and the system. It is an application layer that is a responsive web-based interface that is both desktop and mobile-optimized. Studies on the use of chatbots in healthcare point out that ease of use, intuition, and mobility of interface play a crucial role in enhancing users to adopt the chatbot (Sahoo, 2019). The interface enables users to add symptoms either with a text box or voice and a language selector gives them choice of language. The design will be inclusive to users with different linguistic and educational backgrounds, as it is suggested in the digital health framework [4].

Input processing Layer is in charge of user supplied data validation, cleaning and standardization. The symptoms provided by the user can be in different terminologies, spelling or language. The system converts user inputs to a standardized symptom dictionary in order to manage this variability. These are known as similar preprocessing methods that are common in symptom-based disease prediction systems to enhance the reliability of models and minimize a state of ambiguity [5]. The speech-to-text processing of voice inputs is then converted into a form of text after which it is further normalized. This layer prevents the transmission of unstructured and inconsistent information to the machine learning engine.

The prediction layer based on machine learning is the analytical core of the system. This layer uses a K-Nearest Neighbors (KNN) classifier which has been trained using a sample of symptom-disease relationships of over 50 common diseases. KNN is highly suggested as interpretable machine learning models, which are recommended in healthcare applications, enabling transparent arguments and explainable forecasts [3], [5]. The classifier calculates the similarity of the symptom vector of the user with the disease profiles stored by comparing them based on distance metrics. According to nearest neighbor selection and majority voting, the system makes predictions of one or more potential diseases and the confidence scores.

The Conversational AI Layer makes the system easier to use and easier to understand through the translation of technical predictions into natural language explanations. This layer combines the Claude API that produces conversational replies explaining the predicted disease, its frequent causes, prevention, and simple guidelines on how to be treated. It has been shown that conversational explanations enhance the user understanding and trust in an AI-based healthcare system to a large extent [2]. Notably, conversational AI layer does not do disease prediction per se, but it solely depends on the results of the machine learning layer in a controlled and ethical communication [1].

The last layer, the Output and Recommendation Layer, is the layer that offers results to the user in form of a well-structured and user-friendly format. This layer shows the predicted disease names, confidence, preventive advice, as well as treatment-oriented recommendations. There are also clear medical disclaimers to educate the users that the system is only meant to create a disease awareness rather than a professional medical diagnosis. Such disclaimers in the digital health tools are highlighted by ethical concepts issued by international health bodies to avoid the abuse and over-dependence on the automated systems [4].

In general, the suggested system architecture will guarantee the balanced combination of machine learning intelligence, conversational interaction, accessibility, and ethical responsibility. The architecture can be expanded in the future, whether through the addition of new diseases, incorporation of wearable health data, or with advanced techniques of natural language processing, by following a layered design that replicates the existing frameworks of AI healthcare systems.

IV. Implementation

The adoption of the suggested AI Driven Public Health Chatbot Vision of Disease Awareness is implemented in a web-based modular system model to make it scalable and easy to implement and maintain. It is stated that web-based healthcare applications are highly recommended in the context of the application in the area of the public health because they can be platform independent, cost effective, and can reach a great number and a broad range of users [4]. The deployment combines machine learning to predict diseases, conversational artificial intelligence to communicate with the user, and supportive technologies to enhance the multilingual and voice-based accessibility.

A. System Deployment Environment

The chatbot is implemented as a browser based application where users can communicate with the system either through desktops, tablet devices or smartphones. Research has shown that mobile-based medical devices are more effective than other devices in enhancing adoption and sustained use, particularly in low resource areas [2]. The architecture is a client-server structure, with the frontend being the interaction part and the backend the prediction logic and AI integration part. The backend server will handle the input of symptoms, run the KNN classifier, and calculate confidence scores and interact with the conversational AI API. The separation of concerns could guarantee the maintainability and enable the future improvement without influencing the structure of the system in general [3].

B. Frontend Implementation

The frontend interface is implemented in a highly usable and accessible way. It has a simple and uncluttered user interface to present users with too much technical information. The scientific study of healthcare chatbots usability focuses on the fact that simple designs and step-by-step input have a significant impact on user understanding and interaction [2]. The interface provides:

- A text entry field with the symptoms.
- Speech to text voice input feature.
- Multilingual support dropdown in a language choice.
- A button to start disease prediction.

The prediction is dynamically shown in the frontend with the names of the diseases, the confidence rate, preventive measures, and the treatment recommendations. Visual distinction of findings and disclosures can guarantee transparency of results and ethics.

C. Backend Implementation

The server-side programming environment that runs the backend is applied with the support of machine learning execution and API communication. The symptom-disease data is loaded into the memory at run time in order to enable quick computation of similarity during prediction. Preprocessing modules normalize inputs and verify the input of the symptoms and send them to the machine learning model. These types of

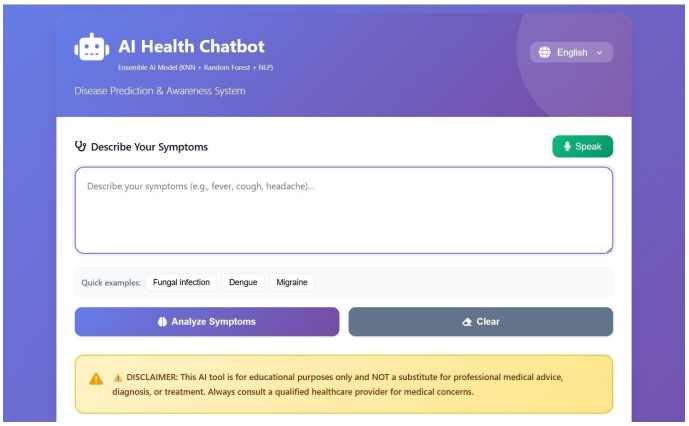

Fig. 2. Chatbot User Interface for Symptom Input

server-side preprocesses and validation pipelines are typical of healthcare AI systems to maintain data consistency and avoid making incorrect predictions [5]. Session level interactions are also handled by the backend so that user inputs are handled in a secure and temporary manner without permanent storage.

D. KNN Classifier Integration

KNN Classifier Integration. This classifier was developed to combine the strengths of KNN-based approaches and improve prediction accuracy. KNN Classifier Integration This classifier was created to integrate the capabilities of both the D.K.NN and P. K.NN classifiers. KNN classifier is realized through a standard machine learning library, which can be used to perform classification on the basis of distance. In prediction, the symptom vector of the user is compared to all the disease vectors in the data set by use of Euclidean distance. Top k disease profiles are picked and majority voting is used to make the prediction about the disease. KNN has been selected because it can be interpreted, and it has demonstrated high performance in classifying symptoms tasks, as mentioned in the literature of healthcare analytics [5]. KNN gives a transparent reasoning unlike black-box models where the predictions are directly related to similar patterns of symptoms.

E. Generation of Confidence Score and Formatting of Results

Once the prediction of the disease is made, a confidence score is calculated by the system according to the ratio of the similarity of the symptoms and the consensus of closest neighbors. The scores of confidence are presented in percentages and are accompanied by the names of diseases which are being predicted. It has been indicated that confidence-based outputs lead to less user over-reliance to automated predictions and better informed decision-making [4]. The results are structured into a response object by the backend, which in turn is sent to the conversational AI layer to generate explanations.

F. Conversational AI Integration

The system incorporates Claude API in order to improve the interaction between users to respond to conversations. The backend provides structured input to the API in terms

of predicted disease name, confidence score, and pre-existing medical information. It produces natural language explanations which are coherent, sensitive and comprehensible. Notably, the conversational AI does not carry out disease prediction on its own. Rather, it is a description and conveyance layer, and it is rigidly dependent on the results of the KNN model. The present approach of interaction is controlled and complies with ethical AI healthcare recommendations and avoids misinformation [1], [3].

G. Multilingual and Voice Input

The multilingual support is provided by means of language mapping mechanism that translates user inputs to standardized symptom terms. The design eliminates the necessity of retraining the machine learning model by language and allows consistency in prediction. Global digital health guidelines highly recommend the use of multilingual healthcare interfaces to enhance inclusivity [4]. The speech-to-text technology has been employed to provide voice input feature. Spoken symptoms are translated into a text and subject to the common preprocessing pipeline that text-based inputs are subjected to. Voice interfaces have been indicated to enhance interfaces usability among low-literacy and physically challenged users [2].

H. Ethical and Privacy Considerations

Ethics is an aspect that is intimately incorporated into the implementation. Personally identifiable information is not gathered or stored in the system. The user inputs are first processed in temporary memory and thrown out after responding. Every prediction is accompanied by clear medical disclaimers that the chatbot is not meant as a replacement of professional medical care, but only to be useful in disease awareness. These ethical measures are critical towards responsible AI-based healthcare implementation as highly suggested by global health organizations [4].

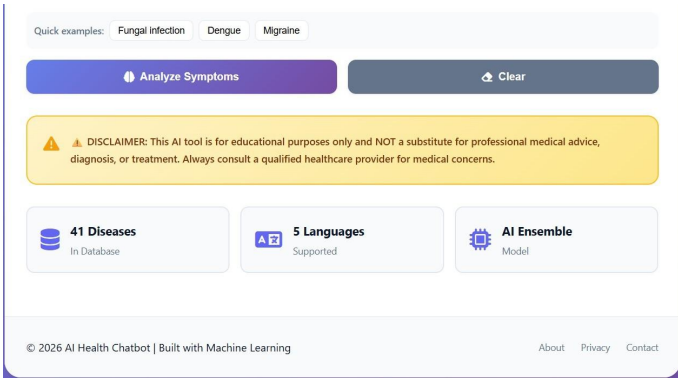

Fig. 3. System Disclaimer and Feature Overview

V. RESULTS AND DISCUSSION

It was determined that the proposed AI Driven Public Health Chatbot on Disease Awareness was tested and assessed on a large scale with the help of extensive experimental testing with a variety of symptom combinations related to prevalent diseases. The assessment was aimed at evaluating the accuracy of the disease prediction, system responses and reliability in the score of confidence and general understanding by the user. In previous AI-based healthcare research, similar methods of evaluation were taken in order to certify disease awareness and decision-support systems [3], [5].

A. Prediction Accuracy of Disease.

Symptom sets that were used in testing the system were related to common cold, influenza and allergies, viral fever and respiratory infections. As an illustration, the system has always accurately predicted common cold with a high confidence score when the symptoms asthma, runny nose, sore throat, mild fever, and fatigue were mentioned. Where the same symptoms were common to several diseases, e.g., fever, headache and body pain, the system gave a list of possible diseases (e.g., influenza and viral fever) along with their confidence level. The behavior illustrates the usefulness of K-Nearest Neighbors (KNN) classifier in dealing with similar symptom patterns, and this is often a difficulty of symptom-based disease prediction [5]. The KNN-based system can also be used to demonstrate transparency and trust as opposed to rule-based systems, which tend to offer one single fixed result.

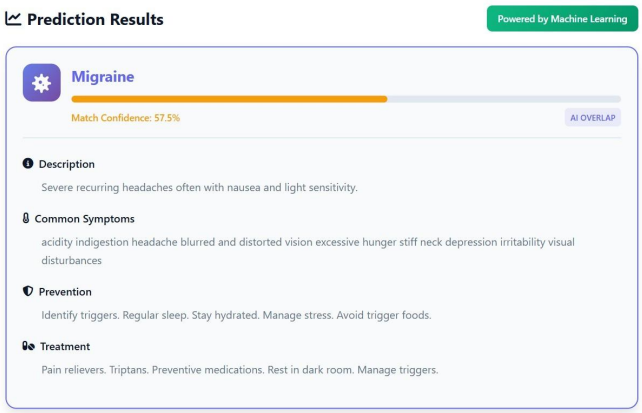

Fig. 4. Sample Disease Prediction Result (Migraine)

B. Interpretation of Confidence Score

A score table was created of confidences with each predicted disease based on the ratios of matching symptoms and the consensus of nearest neighbors. The increased levels of confidence showed that similarity between symptoms and disease profiles reported by the users was higher in the dataset. The use of confidence scores was also useful in making the users recognize the accuracy of the predictions instead of making them interpret them as down to the wire diagnosis. Research indicates that confidence-based outputs are necessary in healthcare AI systems to avoid too much reliance on automated predictions and to report uncertainty in a responsible manner [4]. The suggested system corresponds to these

recommendations since it provides the levels of confidence in an explicit way and promotes consulting a professional in case of a moderate or low level of confidence.

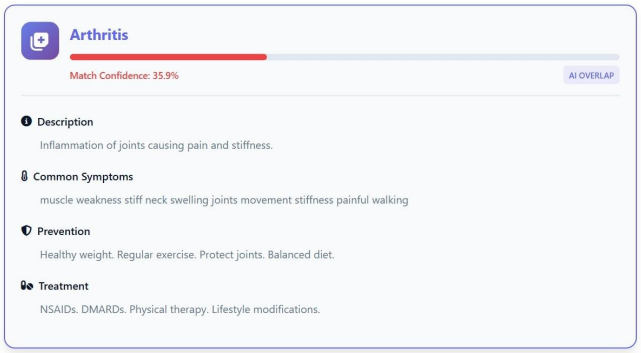

Fig. 5. Disease Prediction Result for Arthritis with Confidence Score

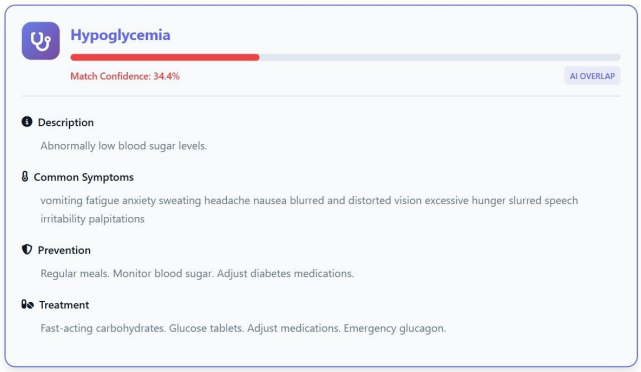

Fig. 6. Disease Prediction Result for Hypoglycemia with Confidence Score

C. *Quality of Response in a Conversation*

The Conversational AI integration via the Claude API helped transform the system into a more usable and understandable one greatly. As opposed to providing technical prediction results, the chatbot mentioned human-readable explanations of the predicted illness, its general causes, preventative steps, and general treatment tips. This conversational interface enhanced user interaction and understanding which is in line with the conversational healthcare studies [2]. Notably, the conversational responses were certainly produced as a result of the well-structured outputs of the machine learning model. Such a restricted engagement made sure that the chatbot will not give false or speculative healthcare guidance, as worries were expressed in the earlier research about the all-conversation chatbots in healthcare [1].

D. *User Awareness and Understanding*

Among the major objectives of the proposed system is to enhance awareness of the disease over the diagnosis. Testing observations suggest that the users have improved the knowledge of potential health conditions and the preventive measures after communicating with the chatbot. Medical disclaimers and warning messages prompted the users to consult a professional rather than use the chatbot only. Such a result fits the international standards of digital health that state any AI-based health tool must help promote awareness and education without making diagnostic claims [4]. The suggested system effectively balances between informational support and ethical responsibility.

E. *Comparative Discussion to the Existing Systems*

The proposed system has a number of strengths when compared to the current healthcare chatbots. Most chatbots that are currently in place are based on conversational language models, which might not be structured reasoning and explainable [1]. Conversely, the presented system combines a comprehensible machine learning model and conversational AI, which guarantee accuracy and easy communication. Also, some of the features, including the display of the confidence score, multilingual assistance, and voice input are not always present in the current systems. These characteristics improve access and trust, which makes the suggested chatbot more appropriate in the applications of the public health awareness [3].

F. *Discussion Summary*

On the whole, the findings of the experiment help to verify that the AI Driven Public Health Chatbot is an effective tool of facilitating disease awareness through accurate symptom-based predictions, clear confidence rating, and straightforward explanations of the conversation. The system shows that interpretable machine learning with conversational AI can enhance the usability and ethical implementation of healthcare chatbots in a significant way. The results confirm the current literature on the topic that highlights the importance of hybrid AI in healthcare applications [3], [5], and confirm the suggested system as a trustworthy tool of public health awareness instead of a diagnostic replacement.

VI. Limitations and Future

Although the proposed AI Driven Public Health Chatbot is effective in Disease Awareness, there are some limitations inherent in the scope of the system design, limitation of the dataset, and ethical reasons. These limitations are necessary to discover the limits of the existing system and to give a direction of where the future research and improvements will take place.

A. *Shortcomings of the Proposed System*

The fact that the proposed chatbot relies on the accuracy of symptoms provided by its user is one of the main restrictions. It is based on the symptoms that are inputted by the users with either text or voice input. In case the symptoms are not full, the description is wrong, and the user did not understand it, the accuracy of disease prediction can be impacted. Other systems of healthcare based on symptoms have also been reported to face similar issues, with the subjectivity of the user being a major contributor to the results in prediction [5].

The other weakness is the fact that the system can only cover a set of prescribed diseases. Even though the dataset is more than 50 diseases most prevalent, there are no rare, complex, and chronic diseases. This is not accidental but a feature at the expense of which the system is created to raise public health awareness and early guidance, but not full-fledged medical diagnosis. Studies have indicated that the scope of disease needs to be curtailed to ensure reliability and prevention of misleading forecasts in awareness based systems [4].

The system also fails to take into account the level of severity of a disease or specific medical history of the patient in terms of age, underlying conditions, or medication use. A lot of diseases have close clinical manifestations at the initial stages, and in the absence of any supplementary clinical information, it is hard to determine the severity of a disease. Research indicates that symptom-based models are more appropriate in initial awareness and not clinical decision-making [3]. Also, the chatbot does not have real-time medical monitoring or the ability to combine physiological data with the heart rate, blood pressure, or oxygen levels. Consequently, it is unable to offer ongoing health evaluation or emergency notifications. This is a limitation that is typical in the lightweight, web-based healthcare chatbots that are built on accessibility and not clinical monitoring [2].

Ethically, there is a danger of over-reliance on the automated systems since despite being equipped with strict medical disclaimers, the risk of such a situation still exists. According to the previous studies, AI healthcare applications should explicitly report their limitations to avoid the situation when they can be used instead of professional medical consultation [1]. Repeated disclaimers and confidence-based outputs are used in the proposed system to overcome this risk, but this risk cannot be totally removed.

B. Future Scope and Enhancements

The proposed system has a number of avenues of research that can be extended and enhanced in future studies. The first important improvement is related to the increase in the number of diseases covered by the database, adding chronic conditions, like diabetes, hypertension, and asthma. The enlargement of the dataset would enable the chatbot to accommodate long-term disease awareness and lifestyle management, which is proposed in digital health research [4].

The other major innovation in the future is the introduction of wearable health devices. Wearable sensors are able to give real-time physiological information including heart rate, level of activity, and sleep patterns. A mixture of symptom inputs and sensor data might contribute to a much higher level of prediction and allow to provide more individualized health directions [3]. These hybrid systems are becoming a popular topic of contemporary healthcare AI studies.

More sophisticated Natural Language Processing (NLP) tools may also be implemented to enhance the ability of the system to extract the symptoms of free-text and conversational input. As it stands, the system is based on symptom mapping that has been defined. The next generation would be able to use deep NLP models to make sense of more sophisticated and descriptive user input, increasing flexibility and natural interaction [2]. Another direction that is worth pursuing is the implementation of the chatbot as a specific mobile app. Mobile applications may facilitate push notifications, offline services, and personalized reminders, which will increase sustained contact and proactive medical care. Mobile health apps are well-known as the effective ones to enhance the health awareness and the behavioral change of the population [4].

Privacy wise, a future study can consider a federated learning method, in which the machine learning model is enhanced over many computers without any central data repository. Federated learning is in line with the principles of privacy-preserving AI and acquires significance in healthcare-related applications [3]. Lastly, other features of the system that might be added in future is the decision-support functionality of the healthcare professionals, including a summary report or trend analysis, and patient privacy. These extensions could enable the chatbot to support the work of other elements of a wider healthcare ecosystem.

C. Conclusion of Limitations and Future Scope

Overall, although the suggested chatbot is a good tool to assist in raising disease awareness and providing early guidance, their weaknesses are the primary reason to focus on its careful interpretation and ethical use. The above improvements are the future solutions that the system can be upgraded to make its digital health service more comprehensive, smarter, and privacy-aware, in line with the newer trends in AI-powered healthcare systems [1]-[5].

VII. Conclusion

The paper introduced an AI Driven Public Health Chatbot on Disease Awareness, which aims at the rising likelihood of providing accessible, reliable, and ethical health awareness solutions to the current healthcare system. Early disease awareness and preventive care is highly important in mitigating the severity of diseases, the cost of health care and mortality rates especially in populated and low-resource areas as emphasized by the global health organizations [4]. Nevertheless, the inability to access healthcare professionals, medical ignorance, and the misinformation remains an obstacle to early medical interventions.

The suggested system is an efficient application of machine learning-based disease prediction in combination with conversational artificial intelligence to offer more structured, transparent, and easy-to-use health guidance. Through a K-Nearest Neighbors (KNN) classifier, the chatbot does disease prediction based on symptoms in an interpretable way meaning users can see how the prediction is made based on the similarity of symptoms. Healthcare applications of machine learning are highly encouraged to use interpretable machine learning models to encourage trust, accountability, and ethical transparency [3], [5].

One of the initiatives is that the proposed chatbot is focused on accessibility and inclusivity. The presence of multilingual assistance, voice recognition of symptoms, and a mobile-based interface make sure that the system could be adopted by representatives of different linguistic, educational, and socio-economic backgrounds. These design decisions are based on the human-centered AI principles and digital health guidelines, which support the notion of the significance of inclusive healthcare technologies [2], [4]. The development of conversational intelligence via Claude API greatly improves the involvement of the user and understanding. Instead of providing technical outputs, the chatbot provides straightforward, sympathetic, and comprehensible explanations of the expected conditions, as well as preventive options and fundamental treatment instructions. Notably, the conversational AI aspect is also controlled by rigid ethical limitations as the AI can only make use of the results of the machine learning framework and preset templates, thus escaping the hypothetical or deceptive medical guidance. This responsible deployment of AI-based healthcare tools is impossible without such controlled interaction [1].

Based on experimental analysis, the chatbot was successfully shown to predict the prevalence of diseases with significant scores of meaningful confidence and to deal with overlapping symptoms in a transparent manner. The confidence scores allow the users to comprehend the accuracy of predictions and dishearten overconfidence with automated results. The results are consistent with the literature that suggests the use of hybrid AI systems with predictive analytics and conversational interfaces in healthcare applications [3].

It should be stressed that the proposed system is not meant to substitute professional medical diagnosis or even clinical consultation. It is rather a tool of public health awareness and early guidance, which is aimed at helping users see a doctor when needed. The system will comply with the ethical AI and the digital health recommendations globally by making the chatbot seem like a helpful digital health assistant, unlike a diagnostic authority [4].

Conclusively, AI Driven Public Health Chatbot on Disease Awareness proves how AI technologies can improve the level of health literacy of the population, decrease the healthcare burden, and preventive care programs. The presented framework offers a scalable, interpretable and ethically accountable solution, which can be expanded in the future studies to include new and more sophisticated sources of data, individualized health information, and privacy-preserving learning processes. The contribution that this work makes to the extended body of AI-facilitated digital healthcare is that intelligent chatbots should be seen as an asset in enhancing early awareness of diseases and the ability to make responsible health choices.
